Experiment Title: Hubble Law
Name: Kevin Grainger
Student No: 20333346
Lab Partner: N/A

Abstract

The aim of this experiment is to find (and visually represent) a relationship between distance and the recessional velocity from two sets of telescope data. The relationship is calculated via linear least squares regression. This relationship is then used to calculate a value for Hubble's constant (H_0).

The first set of data is an older data set with high systematic uncertainty. The calculated value for Hubble's constant serves as a comparison against the more modern and accurate data set.

From the second data set the red-shift from SuperNovas is used to find the recessional velocity. And a distance modulus is used to find the distance values. The resulting Hubble's constant value is a lot more accurate from this data set than the older one.

Data Set 1

Hubble's constant:

Data Set 2

Hubble's constant:

It is observed that the larger distance values in Data Set 2 provide a more accurate H_0 value. By the theory and equations pertaining to Hubble's Law, we can explain:

-A larger distance means systematic errors (from for example the telescope used) have less of an effect on results.

-Over a larger distance the universe is expanding at a greater speed. I.e. there is a larger recessional velocity. Thus as before error is proportionally smaller.

Basic theory & Equations

Hubble's Law:

$$v = H_0 d$$

Where v is recessional velocity, H_0 is Hubble's constant and d is the distance. 

The recessional velocity is calculated using redshift from SuperNovas, as the stretch of light wavelengths is caused by the expansion of space.

$$v = c \frac{(z+1)^2 - 1}{(z+1)^2 + 1}$$

The redshift is relative meaning the relationship is not strictly linear but for small values of red shift we can say that:

$$v = cz$$

Where $z = \frac{\Delta\lambda}{\lambda}$.

In Data Set 2 the distances are expressed in a distance modulus, as such:

$$d = 10^{(\mu/5)+1}$$

Lastly the relationship between regressional velocity (v) and distance (d) is analysed using a linear least squares fit.

The Goodness of Fit: $\sum_{n=1}^N (y_i - y_i^{model})^2$

This is used to measure the accuracy of the best fit line used. This function can be optimised to find the line of best fit or linear regression.

Goodness of fit rewritten: $\sum_{n=1}^N (y_i - mx_i - b)^2$

$$\sum_{n=1}^N (y_i^2 + m^2 x_i^2 + b^2 - 2mx_i y_i + 2bm x_i - 2by_i)$$

This expression can be partially derived to find the y-intercept and slope of the line of best fit. Given as:

N= number of terms

(y-intercept) $b = \frac{\sum y_i - N \sum x_i}{N}$

(Slope) $m = \frac{(N \sum x_i y_i) - (\sum x_i \sum y_i)}{(N \sum x_i^2) - (\sum x_i)^2}$

Apparatus

Logger Pro is used to graph the relationship between Distance and Recessional Velocity.

Both MS Excel and Logger pro were used to create the necessary tables and calculated columns.

Experiment Method:

Data Set 1:

The data set was imported into logger pro. The recessional velocities (kms^{-1}) in Column 2 are plotted against the distances in Column 1 (Mpc). Using the linear fit option in logger pro I found the line of best fit for the data points. This line of best fit is then verified via the goodness of fit and the formulae for the slope and y-intercept. (Derived in 'Equations and Basic Theory').

From the line of best fit equation Hubble's constant is found.
The graph with linear fit overlaid is in 'Data Analysis'.

Data Set 2:

The data set was imported into logger pro. Three calculated columns are created for; Distance (Mpc), Δ Distance (Mpc), Recessional Velocity (kms^{-1}). The functions for Distance (d) and Recessional Velocity (v) are outlined in the lab manual. Respectively:

$$d = 10^{(\mu/5 + 1)}$$

$$v = ZC$$

The Δ Distance (Mpc) function is derived in the 'Error Analysis' section as such:

$$\Delta d = \sqrt{\left(\frac{\ln(10)}{5} (10^{(\mu/5 + 1)}) (\Delta \mu)\right)^2}$$

Once these columns are created and referenced to the correct original columns, graph Recessional Velocity against Distance. (Using Δ Distance as error bars). The linear fit option in logger pro was used again to find the line of best fit. I did not verify this linear fit using 'Goodness of fit' as we already proved the concept using data set 1.

A more accurate value for Hubble's constant was found using the equation of the best fit line.

-To find the age of the observable universe.

We can say that at one point in time Earth and a distant Supernova/Galaxy etc were in the same position in space. That time can be said to be : $t = d/v$

d =distance, v =recessional velocity

$$t = d/(d \cdot H_0)$$

Thus Age of the universe is $= 1/H_0$.

-To find the size of the observable universe

We can no longer see any further into the universe when Recessional

Velocity=Speed of light.

Using $v=H_0d$

$$c=H_0d$$

$$d=c/H_0$$

This creates a spherical 'boundary' around earth, of the size:

$$\frac{4}{3}\pi d^3 = \text{Size of the observable universe.}$$

(2)

Sample of modern supernova data and the calculated columns.

-Distance Column is calculated by: $d = 10^{(\mu/5 + 1)}$, where μ is the column titled mu.

$-\Delta d$ (delta_distance) is calculated via error propagation described in the Error analysis section.

$$\sqrt{\left(\frac{\ln(10)}{5} (10^{(\mu/5+1)}) (\Delta\mu)\right)^2}$$

-Recessional Velocity = zc , where c =speed of light and z =red shift.

Data Analysis:

(3)

$$v=md+c$$

$$v=487.5d+25.75$$

Taking the Hubble Constant as the slope:

$$H_0=487.5$$

(4)

Using the formulae in excel we can verify this from our initial 'Goodness of Fit' Parameter:

$$\text{(y-intercept) } b = \frac{\sum y_i - N \sum x_i}{N}$$

$$\text{(Slope) } m = \frac{(N \sum x_i y_i) - (\sum x_i \sum y_i)}{(N \sum x_i^2) - (\sum x_i)^2}$$

Data Set 2

(5)

Using the best fit line:

$$v = 63.65x + 589.6$$

$$H_0 = 63.65$$

Notice the correlation coefficient is much higher.

(Validity of linear fit proven in Data Set 1 by extension we can accept this best fit)

-Age of the Universe:

Using the most accurate data set where ($H_0 = 63.65$)

$$1/H_0 = 1/63.65 \text{ (km/s/Mpc)}$$

$$\frac{\text{Sec Mpc}}{\text{Km}} * \frac{(3.09 * 10^{19})}{1 \text{ Mpc}} / 3.154 * 10^7 \text{ (sec)}$$

With this all units cancel.

giving :

$$15.39212 * 10^{10}.$$

Or 15.39 billion years

-Finding size of the observable Universe.

We can no longer see any further into the universe when Recessional Velocity = Speed of light.

Using $v = H_0 d$

$$c = H_0 d$$

$$d = c / H_0$$

This creates a spherical 'boundary' around earth, of the size:

$$\frac{4}{3} \pi d^3 = \text{Size of the observable universe.}$$

$$\frac{4}{3} \pi \left(\frac{c^3}{H^3} \right)$$

$$(\text{km/s}) / (\text{km/s}) / (\text{mpc}) = \text{mpc}$$

$$299792 / 63.65 \text{ mpc} = 1.455 \times 10^{23} \text{ km}$$

$$1.455 \times 10^{23} \text{ km} \left(\frac{4}{3} \pi \right) = 8.12844 \times 10^{23} \text{ km} \text{ (Size of obv universe)}$$

Analysis of Accuracy and Uncertainty:

Error Propagation:

Derived from

$$\sigma_f^2 = \left(\frac{\partial f}{\partial x} \right)^2 \sigma_x^2 + \left(\frac{\partial f}{\partial y} \right)^2 \sigma_y^2$$

$$\Delta d = \sqrt{\left(\frac{\partial d}{\partial \mu} \Delta \mu \right)^2}$$

$$\frac{\partial d}{\partial \mu} = \left(\frac{\ln(10)}{5} \right) \left(10^{\frac{x}{5} + 1} \right)$$

(6)

This function is applied in logger pro.

All other uncertainty probably comes from the telescope or spectrometer.

Final Results and Conclusions:

A large disparity was noticed between the data sets.

$H_0=487.5$ For Data Set 1

$H_0=63.65$ For Data Set 2

Data Set 2 Provided a figure much closer to the estimated figure for hubble's constant. (73.8)

Data Set 2 had only 13% error compared to Data Set 1 which had 500% error.

We see the more modern data provided a much more accurate answer. Most likely due to better equipment meaning less systematic error, and longer distances which means error/uncertainty has proportionally much less of an effect on the results.

-Age of the visible universe: 15.39 billion years (14% error)

-Size of visible universe: 8.12844×10^{23} km

Appendices:

(1)= Data set 1 Results

(2)=Data Set 2 Results

(3)=Respective Graph

(4)=Proof for goodness of fit

(5)=Respective graphs

(6)=Error Propagation

Hubble's law can answer the questions such as the age and size of the observable universe.

It provides the true distances between points in the universe as it can account for the expansion.
